Abstract Silver orthophosphate-graphene nanosheets composite (Ag<sub>3</sub>PO<sub>4</sub>-GNs) has been fabricated using a facile hydrothermal method. The Ag<sub>3</sub>PO<sub>4</sub>-GNs were characterized using XRD, UV-vis DRS and SEM. The photocatalytic activity of Ag<sub>3</sub>PO<sub>4</sub>-GNs was evaluated by photocatalytic decolorization of dye aqueous solutions under simulated solar light irradiation. It was observed that Ag<sub>3</sub>PO<sub>4</sub> nanoparticles in Ag<sub>3</sub>PO<sub>4</sub>-GNs were attached on the surface of graphene nanosheets. The introduction of graphene nanosheets enhanced remarkably the visible light absorption region of Ag<sub>3</sub>PO<sub>4</sub>-GNs compared with bare Ag<sub>3</sub>PO<sub>4</sub>. The photocatalytic activity of Ag<sub>3</sub>PO<sub>4</sub>-GNs is nearly twice as high as that of the pure  $Ag_3PO_4$ . The removal efficiency can reach more than 90 % by Ag<sub>3</sub>PO<sub>4</sub>-GNs under simulated solar light irradiation within 25 min, which might mainly be attributed to high adsorption capacity, extended light absorption range and efficient charge separation. After irradiation for 60 min, 84.70 % TOC mineralization was achieved by Ag<sub>3</sub>PO<sub>4</sub>-GNs. Based on

the results of detection of active species, the direct oxidization of dye pollutants in aqueous solution by holes takes a major role in the whole decolorization process by  $Ag_3PO_4$ -GNs. As a result,  $Ag_3PO_4$ -GNs with the high photocatalytic activity are proven to be an excellent light photocatalyst for potentially scalable removal of dyes in aqueous solutions and other environmental remediation under simulated solar light irradiation.

#### Introduction

With rapid industrial developments, a large number of various hazardous pollutants are released into the open environment. Among of those pollutants, toxic organic dyes and their effluents become one of the main sources of water pollution because of the greater demand in textiles, cosmetics and other industries [1, 2]. There are more than 100,000 commercially available dyes with an estimated annual production of over  $7 \times 10^5$  tons of dye-stuff [3]. Industrial dyeing processes lead to the annual discharge of 30,000-150,000 tons of dyes into receiving waters [4]. Effluents from those industries have high content with organic pollutants, salts, chemical oxygen demand (COD), suspended solids (SS) and fluctuating pH [5]. What's more, dye wastewater contains complex composition, making the conventional biological treatment method restricted. As a result, large amount of scientific and technological efforts have been paid toward for effective treatment of those dye wastewater. Among them, photocatalytic oxidation by photocatalysts is found to be one of the most hopeful and most effective methods to degrade dyes wastewater and get rid of them [6, 7].

Very recently, silver orthophosphate  $(Ag_3PO_4)$  semiconductor with a band gap of ~2.3 eV exhibits significant photocatalytic decolorization of organic dyes under visible-light irradiation [8, 9]. Therefore, Ag<sub>3</sub>PO<sub>4</sub> is one of the most promising photocatalysts in harvesting solar energy for clean energy production and environmental purification [8, 10–13]. To further enhance photocatalytic activity of Ag<sub>3</sub>PO<sub>4</sub>, different strategies have been developed [14]. Some composites of  $Ag_3PO_4$ , such as  $SrTiO_3/$ Ag<sub>3</sub>PO<sub>4</sub> [13], Ag<sub>3</sub>PO<sub>4</sub>/CNTs [15], Ag<sub>3</sub>PO<sub>4</sub>/In(OH)<sub>3</sub> [16], and PANI/Ag/Ag<sub>3</sub>PO<sub>4</sub> [14], have been proven significant enhancement of photocatalytic activity for eliminating dye pollutants. Graphene with 2D carbon nanostructures can potentially serve as a support material with which to anchor semiconductors, and to improve the performance of photoelectronic and energy conversion devices [17]. In particular, outstanding conductive ability (mobility of charge carriers 200,000 cm<sup>2</sup> V<sup>-1</sup> s<sup>-1</sup> at room temperature) and an extremely high theoretical specific surface area (theoretically, 2630  $m^2/g$  [18, 19]) can reduce the photo-generated electron-hole  $(e^{-}/h^{+})$  recombination rate and improve the photocatalytic properties of photocatalyst [19, 20]. In recent years, graphene has caught immense research attention to synthesize various graphene/semiconductors and investigate its application for environmental remediation and water purification [21-25]. More recently, Ag<sub>3</sub>PO<sub>4</sub>/ graphene composite [11, 26] and Ag<sub>3</sub>PO<sub>4</sub>/reduced graphene composite [27, 28] have been reported. With the introduction of graphene, the photocatalytic performance and photostability of Ag<sub>3</sub>PO<sub>4</sub>/graphene were greatly enhanced due to the improved separation efficiency of photogenerated carriers and adsorption performance [11, 26]. However, high price of graphene limits its application for practical water treatment. Graphene nanosheets (GNs) are atomic-thickness monolayers of hexagonally arranged,

graphite-derived carbon atoms that may be composed of graphene, graphene oxide, or reduced graphene oxide. They have attracted tremendous interest in their potential application for environmental remediation and water purification [29, 30]. Furthermore, GNs cost only one twentieth of the price of graphene (GNs \$15 g<sup>-1</sup>, graphene \$308 g<sup>-1</sup>). To the best of our knowledge, no previous studies regarding the hydrothermal synthesis and photocatalytic performance of Ag<sub>3</sub>PO<sub>4</sub>-graphene nanosheets (Ag<sub>3</sub>PO<sub>4</sub>-GNs) have been reported.

In this study,  $Ag_3PO_4$ -GNs have been fabricated via a facile hydrothermal method. The composition, morphology, and optical properties of the as-prepared  $Ag_3PO_4$ -GNs were characterized using SEM, XRD and UV-vis DRS. The photocatalytic performance of  $Ag_3PO_4$ -GNs was evaluated by the decolorization of three dyes (congo red, methyl orange and rhodamine B) as model pollutants in aqueous solution under simulated solar light irradiation. Moreover, the possible mechanism for dyes decolorization by  $Ag_3PO_4$ -GNs is proposed based on the experimental results. Our finding can pave a way to develop economical and highly efficient photocatalysts for the removal of organic pollutants for water purification.

#### Materals and methods

#### Chemicals

Graphene nanosheets (GNs, purity >99 %) were purchased from Nanjing Xianfeng Nanomaterial Technology Co., Ltd. Congo red (CR), methyl orange (MO) and rhodamine B (RhB) and used as model dyes were purchased from Yongjia Fine Chemical Factory (Wenzhou, China) (Table 1). Silver nitrate (AgNO<sub>3</sub>, 99 %), sodium hydrogen **Fig. 1** Schematic representation for the preparation of Ag<sub>3</sub>PO<sub>4</sub>-GNs

phosphate ( $Na_2HPO_4$ , 99 %), edetate disodium salt dehydrate (EDTA-2Na), t-butyl alcohol (TBA), sodium hydrate (99 %) and other reagents of analytical grade were purchased from Shanghai Chemical Reagents Research Institute (Shanghai, China) and were used without further purification.

#### Preparation of Ag<sub>3</sub>PO<sub>4</sub>-GNs

Ag<sub>3</sub>PO<sub>4</sub>-GNs were prepared by a simple hydrothermal method (Fig. 1) [9]. Briefly, silver nitrate was dissolved in 200 mL of double distilled water for 1 h. Fifty grams of GNs were ultrasonically dispersed in the double distilled water (50 mL). The resulted GNs suspension was added into the silver nitrate solution. The suspension system was strongly stirred for 12 h. The positively charged Ag<sup>+</sup> cations could be assembled onto the surface of the negatively charged GNs [12]. Na<sub>2</sub>HPO<sub>4</sub> aqueous solution (0.2 M, 10 mL) was added dropwise to the above system with magnetically stirring. The resulting reaction system was then transferred to a Teflon autoclave and heated at 180 °C for 24 h. After the treatment, the obtained precipitate was collected, washed with double distilled water and ethanol for several times and dried at 100 °C under atmospheric conditions for 10 h until constant weight. The corresponding bare Ag<sub>3</sub>PO<sub>4</sub> nanoparticles were also facilely synthesized using the same method but in the absence of GNs.

#### Characterization of Ag<sub>3</sub>PO<sub>4</sub>-GNs

X-ray diffraction (XRD) patterns were measured by a Bruker D8 Advance X-ray diffractometer at 40 kV and 50 mA with Cu target and K $\alpha$  radiation ( $\lambda = 0.154178$  Å) in the region of 2 $\theta$  from 10 to 80°. UV–vis diffuse reflectance spectra (DRS) were collected on a Hitachi UV-3100 UV–vis spectrophotometer with BaSO<sub>4</sub> as the background. Scanning electron microscopy (SEM) images were taken using a Hitachi S4800 scanning electron microscope at specific magnification.

#### **Photocatalytic experiments**

The photocatalytic experiments of congo red (CR), methyl orange (MO) and rhodamine B (RhB) as model pollutants were carried out in aqueous solutions at ambient temperature controlled by a watercooling system. A 300 W Xenon lamp (PLS-SXE300, Beijing Trusttech Co. Ltd., China) was used as a simulated solar light source. The wavelength of simulated solar light irradiation was in a range from 300 to 1100 nm. According to a corresponding technical report of PLS-SXE300, UV output (<390 nm) was about 5.2 % of irradiation energy while visible light output (390-770 nm) was about 39.2 %. 0.05 g of photocatalyst was added to 100 mL of simulating pollutant solution contained in a 250 mL Pyrex glass vessel with a plane side. During reaction, the resulting aqueous suspension containing dye and Ag<sub>3</sub>PO<sub>4</sub>-GNs was continuously stirred and bubbled so that the concentration of dissolved oxygen in the reaction system was kept constant. At given time intervals, about 5 mL aliquots were sampled and centrifuged to remove the photocatalyst. Then concentrations of model pollutants in aqueous solution were determined by a TU 1810 UV-visible spectrophotometer (Beijing Purkinje General Instrument Co., Ltd., China) by monitoring the characteristic absorption wavelength of 553, 463 and 496 nm for RhB, MO and CR, respectively. Decolorization efficiency ( $\eta$ ) of dye solution by Ag<sub>3</sub>PO<sub>4</sub>-GNs at time *t* was calculated by Eq. (1). Total organic carbon (TOC) was measured using a TOC-VCPH analyzer (Shimadzu Co., Japan) to evaluate the mineralization of final dye solutions after the treatments.

$$\eta(\%) = \frac{(C_0 - C_t)}{C_0} \times 100 \tag{1}$$

where  $C_0$  (mg L<sup>-1</sup>) is the initial dye concentration and  $C_t$  (mg L<sup>-1</sup>) is the dye concentrations at a specific given time *t* (min), respectively.

#### **Results and discussion**

#### **Characterization of nanocomposites**

Figure 2 shows XRD patterns of graphene nanosheets (GNs),  $Ag_3PO_4$  and  $Ag_3PO_4$ -GNs. For GNs, the sharp (0 0 2) diffraction peak of GNs at  $2\theta = 26.3^{\circ}$  was found, suggesting that the characteristic interlayer distance of GNs is about 0.34 nm [31]. Furthermore, the XRD pattern of  $Ag_3PO_4$  clearly show that all distinct diffraction peaks ( $2\theta$ ) at 21.1° (1 1 0), 29.9° (2 0 0), 33.5° (2 1 0), 36.8° (2 1 1),

1170

42.7° (2 2 0), 48.0° (3 1 0), 52.9° (2 2 2), 55.2° (3 2 0),  $57.5^{\circ}$  (3 2 1),  $61.8^{\circ}$  (4 0 0),  $66.0^{\circ}$  (3 3 0),  $70.1^{\circ}$  (4 2 0), 72.1° (4 2 1), 74.0° (3 2 2) could be indexed to the bodycentered cubic structure of Ag<sub>3</sub>PO<sub>4</sub> (JCPDS no.06-0505), which agrees well with previously reported work [10, 12, 32, 33]. No other characteristic peak was observed, indicating the high purity of the product formed via a facile hydrothermal method. As for Ag<sub>3</sub>PO<sub>4</sub>-GNs, the above peaks belonging to Ag<sub>3</sub>PO<sub>4</sub> nanocrystal can be clearly indexed, and the peak at 25.3° indexed to (0 0 2) plane of GNs can be found. In the range of  $2\theta = 10-80^\circ$ , no other peaks could be observed, which also confirmed that the composite was exclusively a cubic phase Ag<sub>3</sub>PO<sub>4</sub> crystal and GNs [25]. Notably, the diffraction peak at 26.3° belonging to the separate GNs decreased in the Ag<sub>3</sub>PO<sub>4</sub>-GNs. This results from two facts that the partly disrupted layer-stacking regularity of GNs by the intercalation of Ag<sub>3</sub>PO<sub>4</sub> particles and the very low amount of GNs in the Ag<sub>3</sub>PO<sub>4</sub>-GNs.

UV-vis spectral measurements were employed to measure the changes in the absorption of GNs, Ag<sub>3</sub>PO<sub>4</sub>, Ag<sub>3</sub>PO<sub>4</sub>-GNs and P25, as shown in Fig. 3. GNs has exhibited strong absorption ability in both the visible light and UV light ranges, while bare Ag<sub>3</sub>PO<sub>4</sub> could absorb solar energy with a wavelength shorter than 530 nm [10]. Compared with the bare Ag<sub>3</sub>PO<sub>4</sub>, the Ag<sub>3</sub>PO<sub>4</sub>-GNs display continuous strong absorption in the range of 530-800 nm. A similar result has also been reported on Ag<sub>3</sub>PO<sub>4</sub>/carbon nanotube composite [34]. This suggests that Ag<sub>3</sub>PO<sub>4</sub> particles have been enwrapped by GNs sheets. The possible reason is that the GNs are an excellent light absorptive material and possess a broad absorbance in the visible range. Therefore, as a precondition for effective photodecomposition of organic pollutants, the light absorbing property of Ag<sub>3</sub>PO<sub>4</sub>-GNs composites has been greatly enhanced. Generally, the wider range of light absorption is beneficial to increase the photocatalytic activity of photocatalysts. As a result, the  $Ag_3PO_4$ -GNs composite is suitable to be used for potentially removal of dyes in aqueous solution and other environmental remediation under simulated solar light irradiation.

Figure 4 displays SEM images of GNs,  $Ag_3PO_4$  and  $Ag_3PO_4$ -GNs for evaluation of their morphologies. Figure 4a shows the SEM image of GNs before the attachment of  $Ag_3PO_4$ . GNs have a crumpled layered structure with thin thickness (5–20 nm) and smooth surface, and wrinkled edge [17].  $Ag_3PO_4$  exhibited a body-centered cubic structure with grain sizes of 5–20  $\mu$ m (Fig. 4b), which was accordant with former report. In Fig. 4c, this nanosheet morphology of GNs in  $Ag_3PO_4$ -GNs is retained even after the hydrothermal treatment for 24 h at 180 °C. It was observed that  $Ag_3PO_4$  nanoparticles in  $Ag_3PO_4$ -GNs were attached on the surface of graphene nanosheets. The size of the  $Ag_3PO_4$  in the  $Ag_3PO_4$ -GNs was in micrometer

Fig. 4 SEM images of GNs (a),  $Ag_3PO_4$  (b) and  $Ag_3PO_4$ -GNs (c and d)

secondary pollution in the practical application of photocatalytic technology. In this system, total organic carbon (TOC) was chosen as a mineralization index. After irradiation for 60 min, 84.70 % TOC mineralization was achieved by Ag<sub>3</sub>PO<sub>4</sub>-GNs under simulated solar light irradiation. Obviously, the addition of an appropriate amount of GNs could enhance the photoactivity effectively. The photocatalytic decolorization of CR solution over the photocatalysts matches the pseudo-first-order kinetics by linear transform  $\ln(C_0/C_p) = kt$ . The initial apparent rate constant *k* over Ag<sub>3</sub>PO<sub>4</sub>-GNs is 0.1277 min<sup>-1</sup>, which is nearly two times as high as that of the pure  $Ag_3PO_4$ . Figure 5b shows the temporal evolution of the spectral changes of CR dye solution mediated by  $Ag_3PO_4$ -GNs. As observed from Fig. 5b, absorption spectrum of the original CR solution was characterized by two main bands at 496 and 338 nm. The absorbance peak at 496 nm was attributed to the azo bonds of CR molecule while the absorbance peak at 338 nm was attributed to "benzene, naphthalene rings" structures. During photocatalysis of CR solution by  $Ag_3PO_4$ -GNs, the absorption peak of CR solution at 496 nm decreased gradually and disappeared finally, which is in accordance with

the color change from red to colorlessness of the CR solution with increasing irradiation time. According to the previous report, the azo groups of CR were removed, and then the cycloreversion occurred during the decolorization of CR solution [7]. To clarify whether the adsorption behavior by photocatalysts is responsible for the decolorization of CR solution, the efficiency of adsorption is determined by measuring the evolution of CR dye concentration. The adsorption efficiency of CR by Ag<sub>3</sub>PO<sub>4</sub>-GNs is two times higher than that of bare Ag<sub>3</sub>PO<sub>4</sub>. The carbon in GNs plays important roles during the photocolorization of dye solution by increasing adsorption capacity of Ag<sub>3</sub>PO<sub>4</sub>-GNs. High and fast adsorption of CR on Ag<sub>3</sub>PO<sub>4</sub>-GNs can be attributed to the strong interaction from the  $\pi - \pi$  stacking between aromatic regions of GNs and dye molecular [24], which is profitable for the succedent photocatalytion of CR solution. As a result, the enhanced photocatalytic activity of Ag<sub>3</sub>PO<sub>4</sub>-GNs might be attributed to high adsorption capacity of dyes, extended light absorption range and efficient charge separation due to giant  $\pi$ -conjugation system and two-dimensional planar structure of GNs in Ag<sub>3</sub>PO<sub>4</sub>-GNs.

Furthermore, two other dyes (MO and RhB) were also chosen to evaluate the photocatalytic activity of  $Ag_3PO_4$ -GNs. All the experimental conditions were the same as those of CR decolorization. From the temporal evolution of the spectral changes of MO and RhB solutions mediated by  $Ag_3PO_4$ -GNs under visible light irradiation (Fig. 6a, b), the absorbance spectral lines clearly indicates the gradual, significant and steady decrease in both the absorbance of MO and RhB dyes. The percentage decolorization of MO and RhB at the maximal absorption wavelength was accounted to be 71 and 85 %, respectively, by the end of 120 min of exposure.

#### The proposed photocatalytic mechanism

Generally, the elimination of organic compounds in aqueous solution by photocatalysis can be attributed to both the adsorption and oxidation properties of reactive species, such as  $h^+$  and •OH [35]. To investigate the photocatalytic mechanism of the Ag<sub>3</sub>PO<sub>4</sub>-GNs in more detail, different specific scavengers were used to determinate the influences of •OH and  $h^+$  on the decolorization rates of CR. In this study, *t*-butyl alcohol (TBA) and edetate disodium salt dehydrate (EDTA-2Na), acted as the scavengers for •OH and  $h^+$  [36], were introduced into the photocatalytic process, respectively. Figure 7 shows the corresponding pseudo-first-order rate constants of CR dye over Ag<sub>3</sub>PO<sub>4</sub> and Ag<sub>3</sub>PO<sub>4</sub>-GNs with and without scavengers under simulated solar light irradiation.

At first, the rate constant of CR decolorization by  $Ag_3PO_4$ -GNs composite was 0.1277 min<sup>-1</sup>, which was about twice as high as that of pure  $Ag_3PO_4$  (0.0570 min<sup>-1</sup>). This revealed that the photocatalytic ability of  $Ag_3PO_4$ -GNs composite was higher than that of pure  $Ag_3PO_4$ . For  $Ag_3PO_4$ , the photocatalytic decolorization rate constant was obtained as 0.0570 min<sup>-1</sup> without scavengers, but it

### Author's personal copy

decreased to 0.0519 and 0.0209 min<sup>-1</sup> with the addition of TBA or EDTA-2Na, respectively, demonstrating the contribution of •OH and  $h^+$  with 8.9 and 53.9 %, respectively. As shown in Fig. 7, the addition of TBA almost did not affect the decolorization rate of CR solution by Ag<sub>3</sub>PO<sub>4</sub>, suggesting that •OH was of less importance in the photocatalytic process. However, the decolorization percence of CR solution was still on in the presence of EDTA-2Na under simulated solar light irradiation, indicating some other reactive species besides holes ( $h^+$ ) were involved, such as •HO<sub>2</sub>, •O<sub>2</sub><sup>-</sup>, and so on. In fact, some previous studies have reported that the photogenerated holes of Ag<sub>3</sub>PO<sub>4</sub> cannot oxidize OH<sup>-</sup>/H<sub>2</sub>O to form •OH due to their little difference of potentials [37].

However, for Ag<sub>3</sub>PO<sub>4</sub>-GNs, the photocatalytic decolorization rate constant decreased from 0.1277 to 0.0956 min<sup>-1</sup> and  $0.0118 \text{ min}^{-1}$  with the addition of TBA or EDTA, respectively. With the introduction of GNs to Ag<sub>3</sub>PO<sub>4</sub>, the photocatalytic decolorization of CR solution was obviously suppressed after the addition of TBA. When EDTA (hole scavengers) was added into the photocatalytic system, a notable inhibitory effect on the decolorization activity over the Ag<sub>3</sub>PO<sub>4</sub>-GNs composite was observed, in which less than 10 % rates constant were kept. The same result was also reported by Yang [38]. As is well known, an efficient charge separation/transfer is crucial for the enhancement of photocatalytic activities. The transfer of the holes from valence band (VB) of Ag<sub>3</sub>PO<sub>4</sub>-GNs was accelerated with the addition of GNs. In fact, GNs could act as a support and electron acceptor to suppress the charge recombination of Ag<sub>3</sub>PO<sub>4</sub> and enhance the photocatalytic activity and stability of  $Ag_3PO_4$  [9, 17, 39]. It can be concluded that the direct oxidization of pollutants by holes takes a major role in the whole decolorization process by Ag<sub>3</sub>PO<sub>4</sub>-GNs under simulated solar light irradiation. The high reactive •OH formed in the photocatalytic system was found to be other major responsible for the photocatalytic decolorization of dye solution by for  $Ag_3PO_4$ -GNs.

Based on the results of the addition of active species scavengers, the possible mechanism for photocatalytic decolorization of organic dyes by Ag<sub>3</sub>PO<sub>4</sub>-GNs was proposed and represented in Fig. 8. At first, the objective dye molecular in aqueous solution was adsorbed on the surface of Ag<sub>3</sub>PO<sub>4</sub>-GNs by the strong interaction from the  $\pi$ - $\pi$  stacking between aromatic regions of GNs and dye molecules [40]. It would be easier for the photo-generated active species to oxidize the surface adsorbed dye pollutants. At the same time, the activated  $Ag_3PO_4$  in  $Ag_3PO_4$ -GNs generated electron-hole  $(e^{-}/h^{+})$  pairs in the conduction band (CB) and the valence band (VB) under simulated solar light irradiation, respectively [8]. The excited  $e^{-}$  of photocatalyst could transfer from the conduction band to GNs via a percolation mechanism in GNs-photocatalyst [41, 42] since GNs have been reported to be a competitive candidate for the acceptor material due to its two dimensional  $\pi$ -conjugation structure. During photocatalytic reaction, the aqueous suspension containing both objective dye pollutants and Ag<sub>3</sub>PO<sub>4</sub>-GNs was continuously stirred and bubbled. As a result, the transfer  $e^-$  are scavenged by the dissolved molecular oxygen in dye solution or the adsorbed molecular oxygen on the Ag<sub>3</sub>PO<sub>4</sub>-GNs surface to produce superoxide anion  $(O_2^{\bullet-})$  radicals. The photogenerated  $h^+$  on VB of Ag<sub>3</sub>PO<sub>4</sub> partly oxidize water to form hydroxyl radicals (•OH). At last, together with •OH and  $O_2^{\bullet-}$ , the resultant  $h^+$  in the VB of Ag<sub>3</sub>PO<sub>4</sub> in Ag<sub>3</sub>PO<sub>4</sub>-GNs could undergo chain reactions to degrade and mineralize partially or completely organic dye pollutant in aqueous solution [43].

#### Conclusions

In conclusion, Ag<sub>3</sub>PO<sub>4</sub>-graphene nanosheets composite (Ag<sub>3</sub>PO<sub>4</sub>-GNs) with high performance has been fabricated via a facile hydrothermal method. Ag<sub>3</sub>PO<sub>4</sub>-GNs possessed a wide and extended spectral response, and enhanced charge separation and transportation properties simultaneously. Ag<sub>3</sub>PO<sub>4</sub>-GNs exhibited excellent photocatalytic activity in decolorization of three model contaminants including congo red, methyl orange and Rhodamine B. The enhanced photocatalytic activity of the composite catalysts might be attributed to high adsorption capacity of dyes, extended light absorption range and efficient charge separation due to giant p-conjugation system and two-dimensional planar structure of graphene. Based on the results of detection of active species, it can be concluded that the direct oxidization of pollutants by holes takes a major role in the whole decolorization process by Ag<sub>3</sub>PO<sub>4</sub>-GNs under simulated solar light irradiation. Due to the high activity of Ag<sub>3</sub>PO<sub>4</sub>-GNs composites, it probably has potential applications for environmental remediation and water purification under simulated solar light irradiation.
